Abstract

Background: PAR-2 activation modifies the intestinal motility and takes part in gastrointestinal motility disturbances under intestinal infection or inflammation, but its role in the regulation of normal rectum motility and its change following bacillary dysentery remains unclear.

Methods: Healthy male wistar rats, weighing 200–220 g were paired according to the weight and then divided randomly into control and *Shigella flexneri*-treated groups. *Shigella flexneri* was administered intragastrically in healthy male rats to induce bacillary dysentery. The effect of PAR-2 activation on the normal rectal motility was detected using tension recording system. The change of PAR-2-mediated effect was investigated at different time following the infection.

Results: The activation of PAR-2 induced a dose-dependent relaxation on the rectal longitudinal strips. This effect was TTX insensitive. After the infection with *Shigella flexneri*, the inhibitory effect induced by PAR-2 activation was impaired at day 11 and 18, then recovered to control level at day 25 and 35, besides, the basal mechanical activity of the rectal strips increased at day 11 following infection and recovered to control level at day 18, 25 and 35.

Conclusions: These data indicated that PAR-2 activation regulated the rectal motility and this effect was impaired following bacillary dysentery.

Introduction

In gastrointestinal tract, proteinase-activated receptor-2 (PAR-2) can be activated by endogenous and exogenous proteinases, including mast cell and neutrophil derived tryptase and bacterial and parasite-derived proteinases to modulate inflammation, nociception, permeability, motility, and ion transport [1-5]. Numerous reports have also found that the motility disturbances has close relationship with inflammation, and the alteration and role of PAR-2 in gastrointestinal motility disturbances under intestinal infection or inflammation has also been investigated [6-10]. As we know, PAR-2 activation can modify the colon motility, including enhancement and attenuation [11, 12], it can induces relaxation of guinea pig internal anal sphincter [13], however, the regulatory effect of PAR-2 on the rat rectal motility and its role following bacillary dysentery is uncertain. The aim of the present work was to investigate the role of PAR-2 in the control of rectal

motility and its change after intestinal infection. We hypothesized that PAR-2 inhibited the motility of rectum and this inhibitory effect was changed following the colitis induced by *S. flexneri*. For this purpose, normal and *S. flexneri* infected rats were used to study how rectal motility was affected by the PAR-2 activation under control conditions and in different post infectious phases. Spontaneous and PAR-2 mediated effect were assessed *in vitro* before and after the *S. flexneri* infected by tension recording system.

Material and Methods

Bacteria preparation

Clinical isolates of *S. flexneri* were obtained from Clinical Laboratory, Qi Lu hospital, Ji Nan, China. The strains were routinely grown in blood plate at 37°C, overnight.

Intestinal infection and tissue preparation

All experimental procedures were approved by the Committee on Animal Research and Ethics of Shandong University School of Medicine. The model was established according to our previous work [8]. Briefly, healthy male wistar rats, weighing 200–220 g (provided by Animal Center of Shandong University) were paired according to the weight and then divided randomly into control and *S. flexneri*-treated (SF-treated) groups. Rats received intragastric administration of inocula of 10^8 colony forming units (CFU) in 1 ml of sterile normal saline after an overnight fast (water ad libitum). The rats in the control group were treated with 1ml sterile normal saline. Rats were raised individually in cages and sacrificed by cervical dislocation on days 11, 18, 25 and 35 following the *S. flexneri* treatment. Rectum (0.5 cm from anus, 1–2 cm length) was excised and prepared for tension recording.

Recording of the tension of colonic muscle strips

A segment (1–2 cm length) of rectum was immediately removed from the control and SF-treated rats. The segment was opened along the mesenteric border and pinned flat in a dish filled with oxygenated Krebs solution. Full thickness muscle strips parallel to the long axis of the rectum (4 mm wide, 10 mm long) were prepared and then suspended in a organ bath which was filled with 5 ml Krebs solution, continuously perfused with 95% O₂ and 5% CO₂ and maintained at 37 °C. The muscle mechanical activity was measured by an external isometric force transducer (JH-2B, Instrument Company of Chengdu, Chengdu, China) and a polygraph system (SMUP-PC, Fudan University, Shanghai, China). The muscle strips were required an equilibration for at least 45 min with flushing every 15 min under a preload of 1 g. Then the mechanical response to the PAR-2-AP, SLIGRL-NH₂, and PAR-2 reverse peptide (PAR-2-RP), LRGILS-NH₂ were examined. In some experiments, muscle strips were pretreated with tetrodotoxin (TTX, 10 μM) for 30 min before administration of PAR-2-AP or PAR-2-RP.

Chemicals

PAR-2-AP (SLIGRL-NH₂) and PAR-2-RP (LRGILS-NH₂) were purchased from CL BIO-SCIENTIFIC CO., LTD (Xi an, China). TTX were purchased from Sigma-Aldrich Corp (St Louis, MO, USA).

The Krebs solution was composed of the following reagents (mM):

NaCl 120.6, KCl 5.9, CaCl₂ 2.5, KH₂PO₄ 1.2, MgCl₂ 1.2, NaHCO₃ 15.4 and glucose 11.5.

Statistical analysis

Data are expressed as mean ± SEM. Comparisons between two groups were performed by Student's *t*-test, and comparisons among multiple groups were performed by one-way analysis of variance (ANOVA). $p < 0.05$ was considered as statistically significant. The mean value of the average tension for 3 min period before treatment with PAR-2-AP or PAR-2-RP was taken as the baseline. R value = the average tension for 2, 4, 6, 8, 10 min after each treatment/baseline. For TTX preincubation, baseline was the average tension for 3 min period before the application of PAR-2-AP or PAR-2-RP.

Results

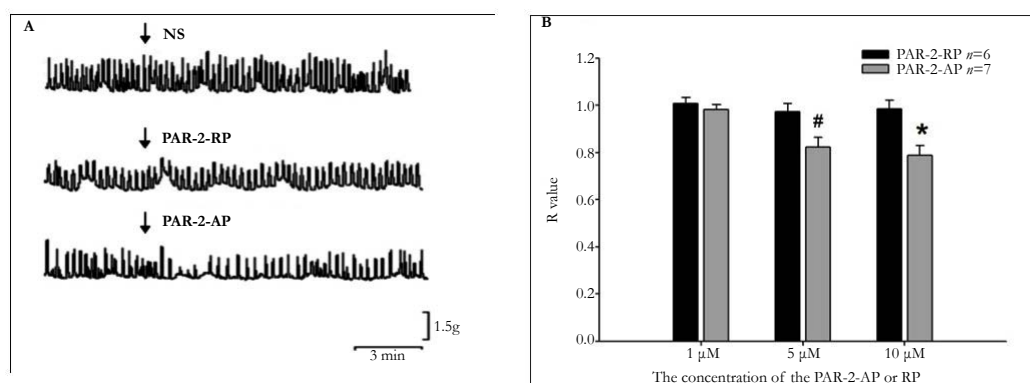

Effect of PAR-2-AP on the spontaneous contraction of longitudinal muscle strips of rectum

PAR-2-AP was shown to inhibit the spontaneous contraction of rectal longitudinal muscle strips, but normal saline (NS) and PAR-2-RP had no apparent effect on the mechanical activity of strips (Figure 1A). Exogenous PAR-2-AP (1–10 μM) dose dependently inhibited the spontaneous contraction of longitudinal muscle strips of rectum at 2 min following PAR-2-AP (5 μM, 10 μM) administration (Figure 1B). The contraction of the rectal muscle strips decreased by 0.176 ± 0.04 ($p < 0.05$ vs RP, $n=7$) and 0.213 ± 0.04 ($p < 0.01$ vs RP, $n=7$) respectively.

Effect of TTX on relaxation evoked by PAR-2-AP on rectal muscle strips

In order to investigate the role of enteric nervous system (ENS) in the relaxation induced by PAR-2-AP, PAR-2-AP and PAR-2-RP were administrated 30 min following the pretreatment of TTX (10 μM), the specific blocker of voltage dependent sodium channels on the membrane of nerve fibers. It seemed that pretreatment of TTX did not influence the inhibitory effect of PAR-2-AP on the contraction of rectal muscle strips (Figure 2).

Figure 1. The inhibition of PAR-2-AP on the spontaneous contraction of rectal muscle strip of rat. The representative recordings of the contraction of rectal muscle strips were shown in A, PAR-2-AP or RP was 10 μM. The dose-response was shown in B. * $p < 0.01$, # $p < 0.05$ vs RP.

Changes in PAR-2-AP induced relaxation following intestinal infection

The 1 μ M PAR-2-AP had no effect on the contraction of rectal muscle strips in both control and SF-treated group (Figure 3), but the inhibition induced by 5 μ M PAR-2-AP significantly decreased in SF-treated group at 11 and 18 days, and this decrease recovered to control level at 25 and 35 days (Figure 3). The impaired relaxation was only observed at 11 days after the administration of 10 μ M PAR-2-AP in SF-treated rats (Figure 3).

Comparison of time course of 5 μ M PAR-2-AP induced relaxation on the rectal muscle strip prepared from control and SF-treated rats

In control group, the 5 μ M PAR-2-AP inhibited the mechanical activity of rectal muscle strips at day 11, 18 and 25, the effective time was shorten accompanied the time (Figure 4 A, B, C). In the infected group, the 5 μ M PAR-2-AP impaired the spontaneous contraction of rectal muscle strips only on day 25 (Figure 4 A, B, C), there was no inhibitory effect on day 11 and 18. On day 35, 5 μ M PAR-2-AP had no effect on rectal muscle strip in both control and SF-treated groups (Figure 4D).

The spontaneous contractility of rectal muscle strips in both control and infectious groups

The spontaneous activity of the rectal muscle strips increased on day 11 post infectious compared to that of the control group. There was no significant difference between control and SF-treated groups on day 18, 25 and 35 (Figure 5).

Discussion

In this study, we described the inhibitory effect of PAR-2 activation on the rectal motility in vitro, we found changes in PAR-2 function in rats following bacillary dysentery. Results obtained showed the impairment in PAR-2 dependent relaxation of rat rectal longitudinal muscle strips on day 11 and 18 postinfection, and this alteration recovered to control level on day 25 and 35 post infection. The basal spontaneous activity of the rectal muscle strips increased on day 11, then returned to control level.

As we know, the function of gastrointestinal tract is affected by the

inflammation or infection, which contributes to the development of functional gastrointestinal disease, such as post infectious IBS. Rectum is vital in defecation, and the alterations in the pattern of defecation is the most common symptom in patients with IBS. It's reported that the compliance, tone and sensation of rectum were changed in patients with IBS [14], and the alterations in rectal sensitivity and motility were observed in children with IBS [15]. Because approximately 1/10 of IBS cases describe a post infectious onset and bacillary dysentery is a causative factor in PI-IBS [16, 17], so it's necessary to investigate the alteration of rectum motility following SF-infection. It's known that PAR-2 has a close relationship with IBS [18], so in our study, we examined the effect of PAR-2 on the motility of rectal muscle. Results showed a dose-dependent relaxation induced by PAR-2 activation. This effect was independent with enteric nervous system indicating the functional expression of PAR-2 on rectal smooth muscle cell. The changed expression and function of PAR-2 was reported in colon in chemical colitis models [9]. In *Trichinella spiralis*-infected (14 and 30 days postinfection) rats, the function and expression of PAR-2 on jejunum were also observed. The PAR-2 induced relaxation of jejunum was enhanced on day 14 postinfection (early phase), and motor responses were normalized on day 30 (early phase) [10]. Here, we also found that the inhibitory effect of PAR-2 on the motility of rectal muscle strip changed at different time post infection. The relaxation induced by PAR-2 activation was impaired on day 11 and 18 postinfection, and according to our previous study [8], there was the early postinfectious phase (11 and 18 days), then the impairment recovered to control level by day 25 and 35 (late phase). Meanwhile, the spontaneous contraction of the rectal muscle strips was tend to increase on day 11 (Figure 5) indicating that the changes in motor of PAR-2 activation associated with the early postinfectious state might have a beneficial role to promote the bacteria expulsion. Interestingly, by day 25 and 35 postinfection, both basal motility and diastolic responses to SLIGRL-NH₂ were normalized. Therefore, changes in PAR-2-mediated motor responses were observed in association with altered basal motility and would contribute to normalize the rectum motility [10]. The change of the PAR-2 expression might be another reason for the impairment of PAR-2 induced relaxation. And several endogenous and exogenous proteinases are candidates to modulate postinfectious changes in PAR-2 expression and functionality. A few studies suggest that PAR-2 dysfunction is originated by a loss of receptors [8-10, 19]. This loss could be related to enhanced levels of proteinases including

Figure 2. The effect of TTX on the inhibitory effect induced by PAR-2-AP. The muscle strips were incubated with TTX (10 μ M) 30 min before the treatment of different concentration of PAR-2-AP or RP.

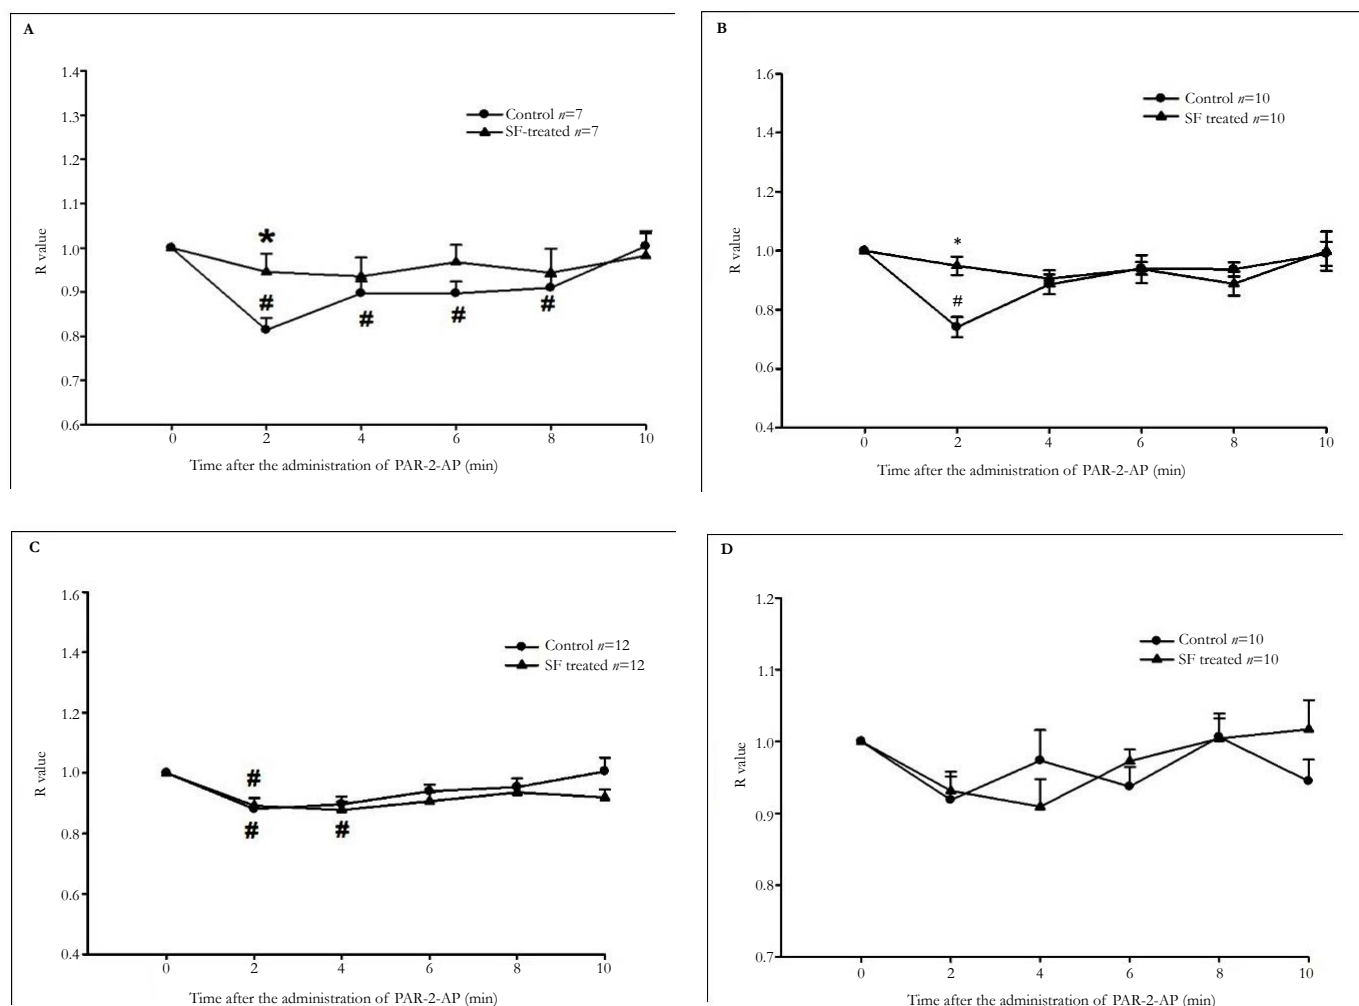

Figure 4. Time course of the inhibitory effect of 5μM PAR-2-AP on spontaneous contraction of the rectal muscle strip prepared from control and SF-treated rats at days 11(A), 18(B), 25(C), 35(D) postinfection. #P<0.05 vs. normalized baseline, *p < 0.05 vs control.

those produced by the bacteria, which would increase PAR-2 activation and internalization leading to a reduced receptor presence on the cell surface [20]. In this respect, the infiltration of neutrophils after the infection of *S. flexneri* is one source of endogenous proteinases. Besides, the expression of PAR-2 was regulated by inflammatory cytokines in rat astrocytes and colon [21, 22] indicated a possible regulatory mechanism existing in the

model of *S. flexneri* infected rat for the release of LPS and other cytokines by bacteria and immune cells, which might contribute to the dysfunction of PAR-2 in our study. Actually in our previous work, the PAR-2 expression was down regulated in distal colon after the infection of *S. flexneri* [8].

Taken together, the contraction of rectal longitudinal strips was

inhibited by the activation of PAR-2, this relaxation effect was impaired on day 11 and 18 postinfectious, the basal contraction of the rectal strips increased on day 11, both the increased basal mechanical activity and the impaired PAR-2-AP induced relaxation returned to normal level on day 25 and 35 postinfectious. These findings are helpful to understand the role of PAR-2 in the development of rectum related disease under inflammation or infection.
